We show that the spin dynamics of the 4–channel Kondo model is equivalent to the one of a model with a spin 1/2 impurity coupled to spin 1 conduction electrons. By abelian bosonization of the latter model we find a kind of Toulouse limit analogous to that recently discussed by Emery and Kivelson for the 2–channel case. We analyse the model by exploiting the close analogy to the problem of an impurity in the Luttinger liquid.

The overscreened multi–channel Kondo model has been the subject of an intensive analysis after Nozières and Blandin’s discovery of its non–Fermi–liquid behavior \[\text{\cite{[1]}}\]. Various methods have been used to tackle this problem: Bethe ansatz technique \[\text{\cite{[2]}}\], large \(n\) (the number of channels) expansion \[\text{\cite{[3],[4]}}\] and conformal field theory \[\text{\cite{[5],[6],[7]}}\]. The main feature of the overscreened Kondo model is a non–analytic temperature and magnetic field dependence of the impurity correction to the free energy, which manifests in the fractional exponents characterizing the power law behavior of, e.g., susceptibility and specific heat. The exact exponents and the asymptotic behavior of the dynamic correlation functions have been determined by means of the Bethe ansatz and conformal field theory.

Recently, Emery and Kivelson found an alternative approach to the problem based on simple abelian bosonization \[\text{\cite{[8]}}\]. It is analogous to the well known Toulouse limit for the standard single channel Kondo model \[\text{\cite{[9]}}\] and allows one to re–obtain all the exact results plus additional information on dynamic properties. However their method is only applicable to the case \(n = 2\).

In this paper we show that a similar approach can be devised for the four channel model. The corresponding Toulouse limit is not exactly solvable on the contrary to the \(n = 1,2\) case. Nevertheless, we are able to determine its low energy properties, which are sufficient to identify all the exponents which control the low temperature behavior of the thermodynamic quantities.

The hamiltonian for the \(n\)–channel Kondo model, \(H = H_0 + H_{\text{exc}}\), consists of the term describing free electrons,

\[
H_0 = v_F \sum_{i=1}^{n} \sum_{\sigma \in \{\uparrow, \downarrow\}} \int_{-\infty}^{+\infty} dx \psi_{i\sigma}^\dagger(x) (-i\partial_x) \psi_{i\sigma}(x)
\]

and the exchange term,

\[
H_{\text{exc}} = \sum_{\alpha=x,y,z} I_{\alpha} S_{\alpha} J^\alpha(0),
\]

where \(I_{\alpha}\) are the exchange constants, \(S_{\alpha}\) are the impurity spin–1/2 operators, and \(J^\alpha(x)\) are the electron spin currents (densities):

\[
J^\alpha(x) = \sum_{i} \psi_{i\sigma}^\dagger(x) \tau^\alpha_{\sigma\sigma'} \psi_{i\sigma'}(x),
\]

\(\tau^\alpha\) being spin 1/2 matrices. As usually \(\text{\cite{[5]}}\), we have retained the s–wave scattering only, linearized the fermion spectrum, and replaced the outgoing and ingoing waves with \(n\)–copies of right–moving electron fields \(\psi_{i\sigma}(x)\) defined for \(-\infty < x < +\infty\). Following \[\text{\cite{[8]}}\] we introduce charge and “flavor” currents,

\[
J(x) = \sum_{i\sigma} \psi_{i\sigma}^\dagger(x) \psi_{i\sigma}(x), \quad \bar{J}(x) = \sum_{ij\sigma} \psi_{ij\sigma}^\dagger(x) t_{ij}^A \psi_{ij\sigma}(x)
\]

\(t_{ij}^A\) being generators of \(SU(n)\) group, and re–write the free part of the hamiltonian as a sum of three commuting terms:

\[
H_0 = \frac{v_F}{2\pi} \int dx \left[ \frac{J(x) \bar{J}(x)}{4n} + \frac{\bar{J}(x) J^A(x)}{n+2} + \bar{J}(x) \bar{J}(x) \right]
\]

This allows one to formulate the problem entirely in terms of the electron spin currents \(\bar{J}(x)\). The information about the number of channels is contained in the commutation relations obeyed by these currents \(\text{\cite{[8]}}\):

\[
\{J^a(x), J^b(0)\} = i e^{abc} \delta^{abc} \bar{J}(x)
\]

(2)

indicating that \(J^a(x)\) form \(SU(2)_n\) Kac–Moody algebra \(\text{\cite{[8]}}\). In order to study magnetic properties, we include also a magnetic field \(h\), which gives rise to an additional term in the hamiltonian

\[
h \left[ S_z + \int dx J_z(x) \right].
\]

Our idea is to model the commutation relations \(\text{\cite{[8]}}\), for particular values of \(n\), by some free fermion representation of the currents, which will eventually be more convenient to work with (in a sense to be specified later) than the original representation given by Eq.\(\text{\cite{[8]}}\).

The following currents:

\[
J^+ (x) = \sqrt{2} \left[ \psi_1(x) \psi_{-1}(x) + \psi_0(x) \psi_0(x) \right],
\]

\[
J^- (x) = \psi_1(x) \psi_1(x) - \psi_{-1}(x) \psi_{-1}(x),
\]

(3)
where $\psi_m(x), m = -1, 0, 1$, are spinless right–moving free electron fields, can be shown to obey the commutation relations (3) with $n = 4$. One can think of Eq. (3) as a representation of spin 1 electron currents.

Since the spin dynamics is completely determined by the commutation relations obeyed by the electron spin currents, we can equally well work with one or the other set of $J^n$'s, Eq. (4) or (5), the spin properties should be the same. This has also an interesting outcome that the spin behavior of the four channel Kondo model is equivalent to the one of a spin 1/2 impurity coupled to spin 1 electrons. The latter problem is interesting by itself, being the simplest realization of a Kondo model with integer spin conduction electrons.

What we are going to show is that the representation (4) has the advantage of having a simple Toulouse limit, which the original representation (5) seems not to exhibit. We bosonize the fermion fields according to

$$\psi_m(x) = (2\pi\alpha)^{-1/2} e^{i\phi_m(x)},$$

where $\phi_m(x)$ are free right-moving Bose fields and $\alpha$ stands for a high-energy cutoff (lattice spacing). Combining these Bose fields as

$$\phi(x) = [\phi_1(x) + \phi_0(x) + \phi_{-1}(x)]/\sqrt{3},$$

$$\phi_s(x) = [\phi_0(x) - \phi_{-1}(x)]/\sqrt{2},$$

$$\phi_f(x) = [\phi_1(x) - 2\phi_0(x) + \phi_{-1}(x)]/\sqrt{6},$$

we see that the field $\phi(x)$ decouples from the impurity, and the part of the hamiltonian, $H_K$, which is relevant for the Kondo effect, takes the form

$$H_K = H_0(\phi_s) + H_0(\phi_f) + \frac{\sqrt{2}I_L}{\pi\alpha} \left[ S_x \cos \left( \frac{\phi_s}{\sqrt{2}} \right) - S_y \sin \left( \frac{\phi_s}{\sqrt{2}} \right) \right] \cos \left( \sqrt{\frac{3}{2}} \phi_f \right) + \frac{I_z}{\sqrt{2\pi}} S_z \partial_x \phi_f + h \left[ S_z + \int dx \frac{1}{\sqrt{2\pi}} \partial_x \phi_s(x) \right],$$

where $H_0(\phi)$ is the free Bose field hamiltonian,

$$H_0(\phi) = \frac{v_F}{4\pi} \int dx |\partial_x \phi(x)|^2$$

and $I_x = I_y = I_{\perp}$ is assumed (for convenience everywhere we do not indicate explicitly the $x$–dependence of the Bose fields, we intend them at the impurity site $x = 0$).

The next step is to employ the canonical transformation:

$$H_K \rightarrow U H_K U^\dagger, \quad U = \exp \{-i S_z \phi_s/\sqrt{2}\}. \quad (5)$$

The transformed hamiltonian reads:

$$H_K = H_0(\phi_s) + H_0(\phi_f) + \frac{\sqrt{2}I_L}{\pi\alpha} S_x \cos \left( \frac{\sqrt{3}}{2} \phi_f \right) + \frac{I_z}{\sqrt{2\pi}} S_z \partial_x \phi_f + h \left[ S_z + \int dx \frac{1}{\sqrt{2\pi}} \partial_x \phi_s(x) \right] + \frac{\hbar}{\sqrt{2\pi}} \int dx \partial_x \phi_s(x),$$

with

$$\delta H = \lambda S_z \partial_x \phi_s, \quad (6)$$

where $\sqrt{2}\pi\lambda = I_z - \pi v_F$. In order to get rid of the bulk contribution of the magnetic field, we shift the Bose field according to

$$\partial_x \phi_s(x) \rightarrow \partial_x \phi_s(x) - \sqrt{2h}/v_F.$$

This shift changes

$$\delta H = \lambda S_z (\partial_x \phi_s - \sqrt{2h}/v_F),$$

and generates a constant $-1/2\chi_0 h^2$ times the length of the system, where $\chi_0 = 1/\pi v_F$ is the uniform spin susceptibility of free conduction electrons.

We see that the line $\lambda = 0$ is indeed analogous to the Toulouse limit for the single–channel Kondo problem and to the Emery–Kivelson line for the two–channel one. Along this line, the canonical transformation (5) leads to the decoupling of the impurity degrees of freedom from the conduction electron ones [the impurity spin component $S_z$ commutes with the hamiltonian (3) and hence loses its dynamics]. However, the hamiltonian for the phase field $\phi_f$ remains nontrivial. Let us write it in the form:

$$H(\phi_f) = H_0(\phi_f) \pm I_{\perp} \cos \left( \sqrt{2\gamma} \phi_f \right) / \sqrt{2\pi} \alpha, \quad (9)$$

where for convention the $\pm$ sign refers to the conserved spin component $S_z$ equal $\pm 1/2$. In our case $g = 3/4$. For the two–channel problem, the same hamiltonian was found with $g = 1/2$ in Ref. [1].

We observe that the hamiltonian (9) is equivalent to the one describing a backscattering of electrons from a single impurity in the spinless Luttinger Liquid. The hamiltonian for this model, expressed in terms of the original Fermi operators, is:

$$H = H_{\text{bulk}} + I_{\perp} \left[ \Psi^\dagger_R(0) \Psi_L(0) + H.c. \right] / \sqrt{2}$$

where the field $\Psi_{R(L)}$ refers to right (left) moving fermions, and $H_{\text{bulk}}$ is the interacting Luttinger liquid hamiltonian. If one bosonizes, according to the standard rules, these Fermi fields and gets rid of the interaction by performing a Bogoliubov rotation, the resulting hamiltonian is indeed Eq. (9). The parameter $g$ in that equation is a measure of the strength of the fermion–fermion interaction, being $g = 1$ for non–interacting fermions and $g < 1 (g > 1)$ for repulsive(attractive) interaction. The problem of an impurity in the Luttinger liquid recently became quite popular in the context of the physics of one–dimensional quantum wires, and it was studied in great detail [10]. We will make use of some known results for this problem to analyse the, as we showed, equivalent Kondo model. Since in the specific case we are considering the parameter $g = 3/4 < 1$, the impurity scattering
operator is relevant and \( I_L \) flows to infinity under scaling transformation. The resulting (stable) fixed point describes a perfectly reflecting barrier, which cuts the system into two semi–infinite lines \( a \) and \( b \). Exactly at the fixed point, that is for everything regarding zero energy and temperature properties, the two regions \( a \) and \( b \) are disconnected. At any finite frequency there is a residual tunneling across the barrier, described by the operator

\[
O = \Psi^\dagger(0)\Psi(0) + \text{H.c.},
\]

where \( \Psi_{a(b)} \) is the electron field referred to region \( a(b) \).

This operator scales to zero approaching the fixed point as \( \omega^{1/2-1} \), with correlation function \( \langle O(t)O(0) \rangle \sim t^{-2/g} \) (see Ref. [10]).

Coming back to the Kondo model (3) and (4), we notice that on the line \( \lambda = 0 \) the total uniform susceptibility \( \chi \) coincides with \( \chi_0 \), that one of the conduction electrons in the absence of the magnetic impurity. Thus the impurity susceptibility defined as \( \chi_{imp} = \chi - \chi_0 \) vanishes on this line (the same occurs at the equivalent line of two–channel Kondo model [32]). Similarly the impurity contribution to the total specific heat at \( \lambda = 0 \) vanishes. Therefore, in order to study the physical properties of the Kondo model we need to perform a perturbation expansion in the correction \( \delta H \), Eq. (5), to the hamiltonian (4) around the solvable line \( \lambda = 0 \) (11).

As a first step, we calculate the dimension \( x \) of the impurity spin \( S_z \), which determines the large time decay of the correlation function

\[
\langle T(S_z(t)S_z(0)) \rangle = C t^{-2x},
\]

where \( C \) is a numerical coefficient.

Since \( S_z \) is a sum of lowering and raising operators for the states labeled by the \( S_z \) component of the spin, its effect is simply to reverse the sign of the backscattering potential \( I_L \) in the hamiltonian (11). Therefore the problem of finding the dimension of \( S_z \) is similar, but not exactly equivalent, to the problem of calculating the \( x \)–ray edge exponents in the Luttinger liquid. The latter problem corresponds to a sudden switching of the backscattering potential on/off and has recently been studied [17]. The difference in our case is that, instead of switching on/off the scattering potential, we must cope with the sudden change of its sign. For non–interacting electrons \( g = 1 \) the dimension of this operator can easily be calculated by a standard approach based on phase–shift arguments [12], and it turns out to be \( x = 1/4 \). For the value \( g = 1/2 \) the exponent \( x = 1/2 \) was recently found in Ref. 11. For arbitrary \( g \leq 1 \), we find \( x = 1/4g \). This result, although related to the \( x \)–ray edge singularity, differs in a striking way, specifically the maximum value of the exponent is not bounded by the scattering phase shift value in the unitary limit.

The exponent \( x = 1/4g \) is calculated by noticing that the unitary operator \( W = \exp\{i\pi J_z/2\} \) changes sign of the backscattering potential provided that the operator \( J_z \) is the total fermionic current [4], which is defined as the difference between the total numbers of right and left moving fermions and satisfies

\[
[J_z, \phi_f(x)] = i\sqrt{2g}.
\]

Therefore

\[
\langle T(S_z(t)S_z(0)) \rangle \propto \langle T(W(t)W(0)) \rangle.
\]

Due to the backscattering potential, the current \( J_z \) is not a conserved quantity but acquires a dynamics which has been analysed in Ref. [4]. From this analysis, \( J_z \) turns out to be essentially a gaussian variable with correlation function behaving at large time as

\[
\langle T(J_z(t)J_z(0)) \rangle = (2/\pi^2g) \ln t.
\]

Hence the dimension of \( W \) (i.e. \( S_z \)) is indeed \( x = 1/4g \). The dimension of the operator \( \delta H \), Eq. (6), is \( 1+1/4g > 1 \), thus being irrelevant at the stable zero temperature fixed point \( \lambda = 0 \), \( I_L = \infty \). The finite temperature behavior of the system is described by the irrelevant operators which move the hamiltonian away from this fixed point, specifically the operator \( \delta H \), which brings the system away from \( \lambda = 0 \), and the operator \( \lambda O \) [see Eq. (10)], corresponding to a deviation from \( I_L = \infty \), where \( \lambda \) is a non–universal parameter. As we showed, the former operator has dimension \( 1+1/4g \) and the latter one has dimension \( 1/4g \). For our case, \( g = 3/4 \), the two dimensions coincide, which implies that both operators have to be considered on equal footing. The two–channel Kondo model corresponds to \( g = 1/2 \), then \( O \) is more irrelevant than \( \delta H \) and can be neglected.

Armed with this results, we can evaluate the first non–vanishing correction to the free energy due to a finite \( \lambda \) and \( \lambda \) in the presence of a magnetic field. The contribution proportional to \( \lambda^2 \) is

\[
\delta F^{(\lambda)}_{imp} = -\frac{1}{2} \int_0^\beta d\tau \langle [\delta H(\tau)\delta H(0)] \rangle = -\frac{\lambda^2}{2} \int_0^\beta d\tau \langle [\delta H(0)] \rangle,
\]

\[
\langle [\delta H] \rangle = \langle [\delta H(0)] \rangle
\]

\[
\beta \text{ being the inverse temperature } T. \text{ Since } \phi_s \text{ and } S_z \text{ are independent, the above correlation function factorizes, and, by substituting the imaginary time representation of the correlation function (11), we obtain}
\]

\[
\delta F^{(\lambda)}_{imp}(T, h) = \frac{(\lambda C)^2}{2} \int_0^\beta d\tau \left[ \frac{\pi/\beta}{\sin(\pi \tau/\beta)} \right]^{2x} \left[ \frac{2\hbar^2}{v_F} + \frac{1}{v_F} \left[ \frac{\pi/\beta}{\sin(\pi \tau/\beta)} \right]^2 \right].
\]
The term proportional to $h^2$, which defines the magnetic susceptibility, is convergent ($x = 1/3$). The other term, whose temperature dependence relates to the specific heat, is instead singular, and needs to be regularized by introducing an ultraviolet cut-off. The cut-off dependent part is analytic in temperature (actually it is a constant apart from $O(T^2)$ terms), so that the regularization procedure does not affect the leading non-analytic $T$ dependence of the free energy. The result is
\[
\delta F^{(\lambda)}(T, h) - \delta F^{(\lambda)}(0, 0) = -\lambda^2 A \left[ T^{2x+1} + \frac{2x+1}{\pi^2 x} \lambda^2 T^{2x-1} \right] + O(T^2),
\]
where the coefficient
\[
A = -\frac{\pi C^2}{v_F^2} \left( \frac{\pi}{2} \right)^{2x} \frac{x}{2x + 1} \frac{\Gamma^2(1/2 - x)}{\Gamma(1 - 2x)}.
\]

Analogously the contribution to the free energy proportional to $\tilde{\lambda}^2$ is:
\[
\delta F^{(\tilde{\lambda})}(T, h) - \delta F^{(\tilde{\lambda})}(0, 0) = \tilde{\lambda}^2 AT^{2x+1}.
\]

By substituting the value $x = 1/3$ into the above expressions, we get the impurity contribution to the specific heat and susceptibility:
\[
C_{\text{imp}} \propto T^{2/3}, \quad \chi_{\text{imp}} \propto T^{-1/3},
\]
in agreement with exact critical exponents found by different methods. Another quantity of physical interest is the Wilson ratio, which can also be evaluated, and for which we find
\[
R_W = \frac{T \chi_{\text{imp}}/C_{\text{imp}}}{T \chi_0/C_0} = \frac{12\lambda^2}{\lambda^2 + \lambda^2},
\]
where the bulk value is taken as $T \chi_0/C_0 = 3/(4\pi^2)$. It is worthy to note that, as follows from our solution, the Wilson ratio is not universal (in spite of the spin degrees of freedom have been kept decoupled from the charge and flavor ones). Since $\lambda$ describe how one moves away from the fixed point in the $I_z$ and $I_\perp$ directions respectively, the non universality of $R_W$ simply reflects the spin anisotropy. In the spin isotropic case the value $R_W = 8$ was found in Ref. [8]. The relevance of the spin anisotropy in the four channel model is a consequence of the operators $\delta H$ and $O$ having the same dimension. This contrasts to what happens in the two channel model, where only the former operator contributes, and in the conventional single channel Kondo model [3], in both cases spin anisotropy does not affect the Wilson ratio.

To conclude, we have shown that the Toulouse limit can be realized in the four channel Kondo model or, equivalently, in the model where spin 1 conduction electrons couple to a spin 1/2 impurity.

We are thankful to A. M. Sengupta for helpful discussions and important suggestions.

[9] From the conformal field theory point of view, the possibility of formulating the 4-channel Kondo problem in terms of two Bose fields, Eq.(4), is related to the fact that the central charge of $SU(2)_c, c = 2$, is equal to that of one of two Bose fields $\tilde{\lambda}$. Another candidate for a simple abelian formulation is the 10-channel Kondo problem with $c = 5/2$.
[13] This is the real current which couples to an electromagnetic field, not to be confused with the current densities we defined throughout the text.
